Abstract: WSN consists a large number of dispersed and dedicated sensors in order to sense the physical conditions of the environment like sound, temperature, humidity, pollution levels and pressure and so on. Routing protocols in WSNs are broadly classified as, Hierarchical routing protocols (HRP), Quality of service based routing protocols, Location Based routing protocols and Flat based routing protocols. Hierarchical routing is an efficient method to less energy consumption within a cluster and by performing data collection and fusion in order to limit the number of transmitting messages to the BS. LEACH and PEGASIS are the hierarchical based routing protocols. PEGASIS is a chain based routing protocol, which is an enhancement of LEACH protocol. It saves a huge amount of energy compared with the LEACH by upgrading the delivery method of information.

Keywords: WSN; HRP; LEACH

I. INTRODUCTION

Wireless sensor networks (WSN) sometimes called wireless sensor and actuator networks (WSAN) are spatially distributed autonomous sensors to monitor physical or environmental conditions, such as temperature, sound, pressure, etc. and to cooperatively pass their data through the network to a main location. The more modern networks are bi-directional, also enabling control of sensor activity. The development of wireless sensor networks was motivated by military applications such as battlefield Surveillance; today such networks are used in many industrial and consumer applications, such as industrial process monitoring and control, machine health monitoring, and so on. The WSN is built of "nodes" – from a few to several hundreds or even thousands, where each node is connected to one (or sometimes several) sensors. Each such sensor network node has typically several parts: a radio transceiver with an internal antenna or connection to an external antenna, a microcontroller, an electronic circuit for interfacing with the sensors and an energy source, usually a battery or an embedded form of energy harvesting. A sensor node might

vary in size from that of a shoebox down to the size of a grain of dust, although functioning "motes" of genuine microscopic dimensions have yet to be created. The cost of sensor nodes is similarly variable, ranging from a few to hundreds of dollars, depending on the complexity of the individual sensor nodes. Size and cost constraints on sensor nodes result in corresponding constraints on resources such as energy, memory, computational speed and communications bandwidth. The topology of the WSNs can vary from a simple star network to an advanced multi-hop wireless mesh network. The propagation technique between the hops of the network can be routing or flooding

Figure 1 shows the structural views of a sensor network in which sensor nodes are shown as small circles. The sensor nodes consist of the four components such as:

- ✓ Sensor unit
- ✓ Central processing unit (CPU)
- ✓ Power unit
- ✓ Communication unit

Each component performs different tasks. The sensor unit is responsible for collecting information as the ADC requests and returning the analog data it sensed. The sensor unit

consists of sensor and ADC (Analog to Digital Converter). ADC is used to inform CPU that what the sensor unit has sensed, and also to instruct the sensor unit to perform next step.

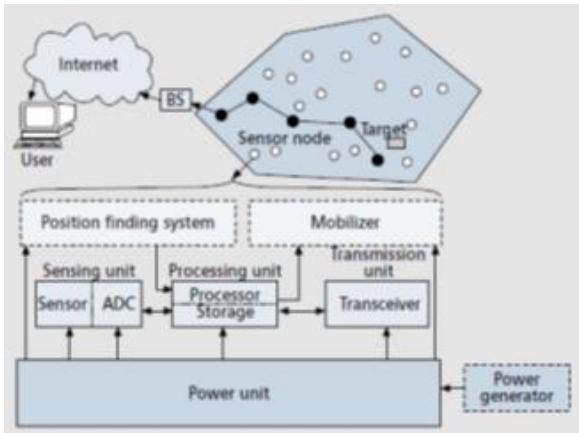

Figure 1: Structural view of a sensor network [1]

The sensors are classified into three categories:

PASSIVE, OMNI DIRECTIONAL SENSORS: Passive sensors sense the data without actually manipulating the environment by active probing. They are self powered i.e. energy is needed only to amplify their analog signal. There is no motion of "direction" involved in these measurements.

PASSIVE, NARROW-BEAM SENSORS: These sensors are passive but they have well-defined motion of direction of measurement. Typical example is 'camera'.

ACTIVE SENSORS: These groups of sensors actively probe the environment, for example, a solar or radar sensor or some type of seismic sensor, which generate shock waves by small explosions.

Communication unit is used to receive command or query from and transmit the data from CPU to the outside world. CPU is the most complex unit. It Interprets the command or query to ADC monitors and controls power if necessary, processes received data, computes the next hop to the sink, etc. Power unit supplies power to sensor unit, processing unit and communication unit. Each node also consists of the two optional components like Location finding unit and Mobilizer. If the user requires the knowledge of location with high accuracy then the node should get information from Location finding system and Mobilizer.

The basic goals of a WSN's are to determine the value of physical variables at a given location, detect the occurrence of events of interest, and estimate parameters of the detected event or events and classify a detected object, track an object.

Thus the important requirements of a WSN's are use of a large number of sensors, attachment of stationary sensors, low energy consumption, collaborative signal processing, self-organization capability, and querying ability.

The characteristics of sensor networks and application requirements have effect on the network design objectives with respect to network capabilities and network performance. As compared to the traditional wireless communication networks such as mobile ad hoc network (MANET) and cellular systems, wireless sensor networks have the following unique characteristics and constraints:

- ✓ Battery-powered sensor nodes

- ✓ Dense sensor node deployment
- ✓ Sensor node's energy, its computation and storage constraints
- ✓ Self-configurable
- ✓ Data redundancy
- ✓ Many-to-one traffic pattern
- ✓ Frequent topology change
- ✓ Application specific

These WSNs may consist of heterogeneous and mobile sensor nodes; the network topology may be as simple as a star topology. The scale and density of a network varies depending on the application. To meet all the requirements the following are the important design issues of the sensor network have to be considered [2]

- ✓ Fault Tolerance
- ✓ Scalability
- ✓ Production Costs
- ✓ Operating Environment
- ✓ Power Consumption
- ✓ Data Delivery Models
- ✓ Data Aggregation/Fusion
- ✓ Quality Of Service (QoS)
- ✓ Data Latency And Overhead
- ✓ Node Deployment

II. CLASSIFICATION OF ROUTING PROTOCOLS

The routing algorithms for WSNs can classify in many different ways. Routing protocols are classified as:

Based on data collection	Based on response	Based on initiation	Based on the sensor network architecture
Node centric	Reactive routing protocol	Destination initiated (Destination-Initiated)	Homogeneous node
Data-centric	Proactive routing protocol	Source initiated (Source-initiated)	Heterogeneous node
Location-aware (geo-centric)	---	---	---
QoS based routing protocols	---	---	---

Table 1: Classification of routing protocol [3]

Most of the Ad-hoc network routing protocols are node-centric protocols where destinations are specified based on the numerical addresses (or identifiers) of nodes. In WSNs, node centric communication is not a commonly expected communication type. Therefore, routing protocols designed for WSNs are more data-centric or geocentric.

In data-centric routing, the sink sends queries to certain regions and waits for data from the sensors located in the selected regions. Since data is being requested through queries, attribute based labeling is necessary to specify the

properties of data. Here data is usually transmitted from every sensor node within the deployment region with significant redundancy.

In location aware routing, nodes know where they are in a geographical region. Location information can be used to improve the performance of routing and to provide new types of services.

In QoS based routing protocols, the data delivery ratio, latency and energy consumption are mainly considered to get a good QoS (Quality of Service), the routing protocols must possess more data delivery ratio, less latency and less energy consumption.

Routing protocols can also be classified based on whether they are reactive or proactive. A proactive protocol sets up routing paths and states before there is a demand for routing traffic. Paths are maintained even there is no traffic flow at that time. In reactive routing protocol, routing actions are triggered when there is data to be sent and disseminated to other nodes. Here paths are setup on demand when queries are initiated.

Routing protocols are also classified based on whether they are destination-initiated (Destination-initiated) or source-initiated (Source-initiated). A source-initiated protocol sets up the routing paths upon the demand of the source node, and starting from the source node. Here source advertises the data when available and initiates the data delivery. A destination initiated protocol, on the other hand, initiates path setup from a destination node.

Routing protocols are also classified based on sensor network architecture. Some WSNs consist of homogenous nodes, whereas some consist of heterogeneous nodes. Based on this concept we can classify the protocols whether they are operating on a flat topology or on a hierarchical topology.

In Flat routing protocols all nodes in the network are treated equally. When node needs to send data, it may find a route consisting of several hops to the sink. A hierarchical routing protocol is a natural approach to take for heterogeneous networks where some of the nodes are more powerful than the other ones. The hierarchy does not always depend on the power of nodes. In Hierarchical (Clustering) protocols different nodes are grouped to form clusters and data from nodes belonging to a single cluster can be Combined (aggregated).

The clustering protocols have several advantages like scalable, energy efficient in finding routes and easy to manage.

III. ROUTING PROTOCOLS IN WSN

Routing used in wireless sensor networks differs from conventional routing which is used in fixed networks in various ways. In WSNs, there is no infrastructure, wireless links are unreliable, sensor nodes may fail, and routing protocols have to meet strict energy saving requirements.

IV. LEACH PROTOCOL

Low energy adaptive clustering hierarchy (LEACH) is routing algorithm proposed to collect and deliver data to the sink, called a base station. The main purposes of LEACH are:

- ✓ Expansion of network lifetime
- ✓ Reduced energy consumption by each network sensor node
- ✓ Use of data aggregation to reduce the number of communication messages.

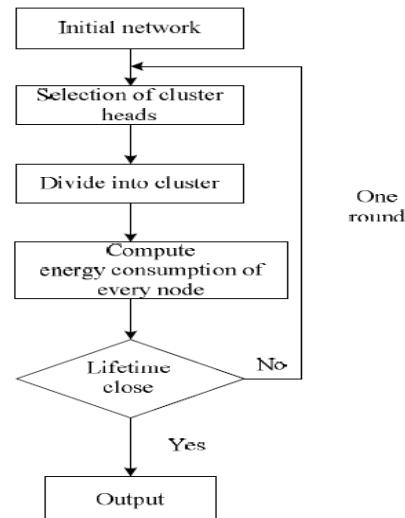

Figure 2: Hierarchical approach of LEACH protocol

To achieve these purposes LEACH adopts a hierarchical approach to arrange the network into a group of clusters. Each cluster is managed by a chosen cluster head. The cluster head has the responsibility to carry out multiple tasks. The first task is the periodic collection of data from members of the cluster. After gathering data, the cluster head aggregates it to remove redundancy among correlated values. The second task of CH is to transmit the aggregated data directly to the base station. The transmission of the aggregated data is takes place over a single hop.

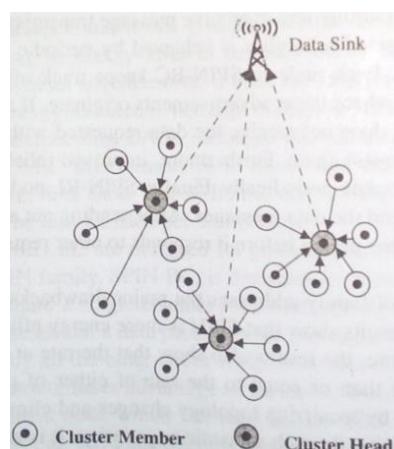

Figure 3: LEACH Network Model

The network model used by LEACH is as shown in figure 3. The third main job of the cluster head is to create a TDMA-based schedule whereby each node of the cluster is assigned a time slot so that it can be used for transmission of data. The cluster head advertises TDMA schedule to its cluster members

through broadcasting. To reduce the collisions among sensors within and outside the cluster, LEACH node use a code division multiple access-based scheme for communication.

Many routing algorithms were developed for wireless networks in general. There are some hierarchical protocols in WSN like LEACH and PEGASIS

The basic operations of LEACH are structured in two different phases. These phases are as shown in figure 4. The first phase called set up phase, consists of two steps, cluster head selection and cluster formation. The second phase called the steady state phase which focuses on data collection, aggregation and delivery to the base station. The duration of the set up is assumed to be relatively shorter than the steady state phase to minimize the protocol overhead.

At the start of the set up phase, a cluster-head selection starts.

The cluster-head selection process role rotates among sensor nodes, by distributing energy consumption evenly across all network nodes. To determine each the sensor node turn to become a cluster head, a node 'n' generates a random number v between 0 and 1 and compares it to the cluster head selection

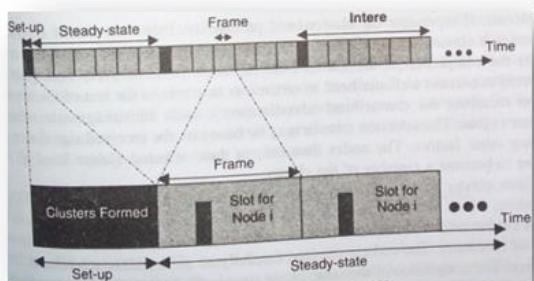

Figure 4: LEACH operation Phase cycle

threshold $T(n)$. The CH selection threshold is calculated to ensure with high probability that a predetermined fraction of nodes, P is chosen cluster heads at each round. Further, the threshold ensures that nodes which served in the last $1/P$ rounds are not selected in the current round.

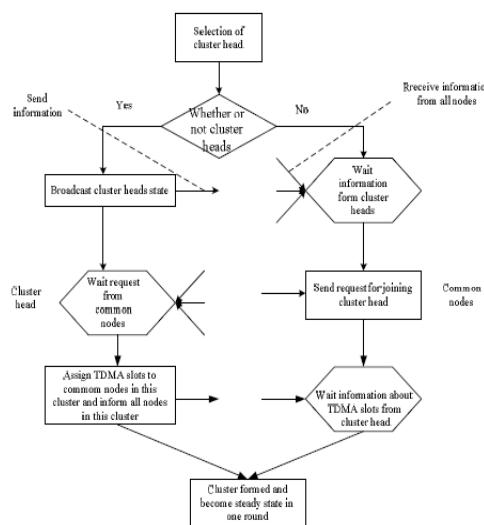

Figure 5: Cluster formation of LEACH protocol

To meet these necessities, the threshold $T(n)$ of a competing node n can be expressed as follows:

$$T(n) = 0 \quad \text{if } n \notin G \\ = P/1-P(r \bmod (1/p)) \quad \forall n \in G$$

The variable G represent the set of nodes that have not been selected as cluster heads in the last $1/P$ rounds and r denotes the existing round. The predefined parameter, P represents the cluster-head probability. It is obvious that if a node has functioned as a cluster head in the last $1/P$ rounds then it will not be chosen in this round.

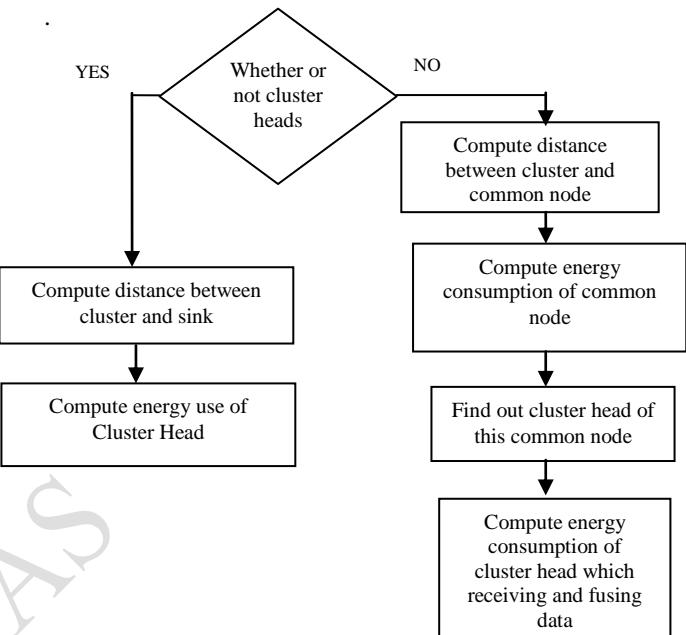

Figure 6: Different processes of nodes in LEACH protocol

During the completion of the cluster-head selection process, every node which was selected to become a cluster-head advertises its new role to the remaining of the network. After receiving the CH advertisements, each remaining node selects a cluster to join. The selection criterion is based on the received signal strength. The nodes then inform their selected cluster head of their wish to become a member of that cluster

After cluster formation, each cluster head creates and distributes the time slots allocated for each member of the cluster in TDMA schedule. Each CH also selects a CDMA code and distributed to all members of its cluster. The code is selected cautiously so as to reduce intercluster interference. The completion of the set up phase signals there is beginning of the steady state phase. During this phase, nodes collect information and use their allocated slots to transmit to the cluster head the data collected. This data collection is performed periodically.

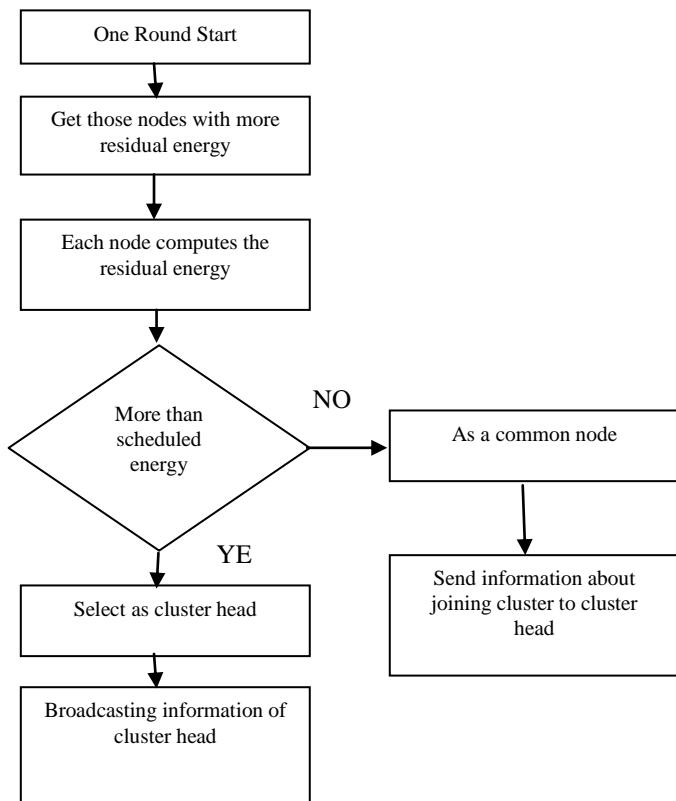

Figure 7: Cluster-Head selection of LEACH protocol

Simulation results show that LEACH achieves significant energy savings. These savings depend primarily on the data aggregation proportion achieved by CHs. It also outperforms conventional routing protocols including direct transmission and multihop routing.

V. SIMULATION PARAMETER

NS 2.35 simulation software is used for simulating different hierarchical routing protocols.

$E_{elect} = 50 * 0.000000001$	Energy being dissipated to run transmission in joules/bit
$E_{fs} = 10 * 0.000000000001$	Energy lost on forwarding
$E_{amp} = 0.0013 * 0.000000000001$	Energy dissipated in transmission amplifier
Dist4mBS2node 200	Coverage area & Node energy allotted to each node is 2joules/bit
$E_{ch} = 50 * 0.000000001$	Energy of cluster
$EDA = 5 * 0.000000001$	Energy lost on delay

VI. SIMULATION RESULTS AND ANALYSIS

This section describes the simulation tool, simulation parameters and simulation results. The performance of routing protocol was evaluated on the basis of three performance metrics: Bits from cluster, Number of frames per round number and number of alive nodes.

Simulation Tool: NS2 (Network Simulator version 2) [5] [6] [7], is a packet level discrete event simulator; developed by UC Berkeley is a widely used tool for computer simulations. It's becoming one of the first selected software to implement network simulation in the academic field. NS2 is a software package including some basic components like Tcl/Tk, OTcl, NS2, Tclcl, etc. As shown in the Figure 8 the basic structure of NS-2 is consist of:

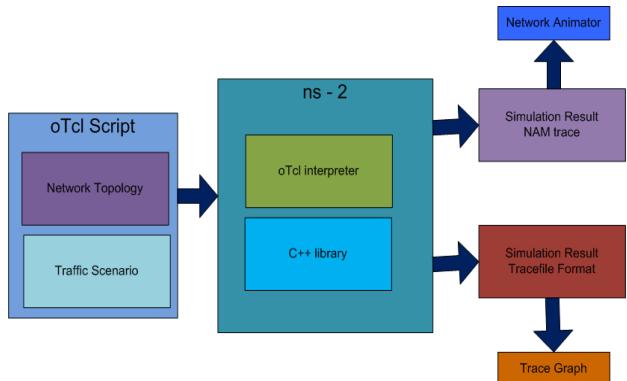

Figure 8: Basic structure of NS-2

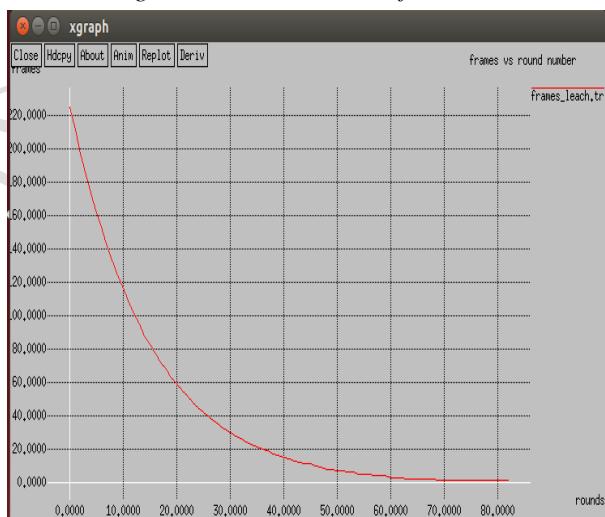

Figure 10: frames vs. round number

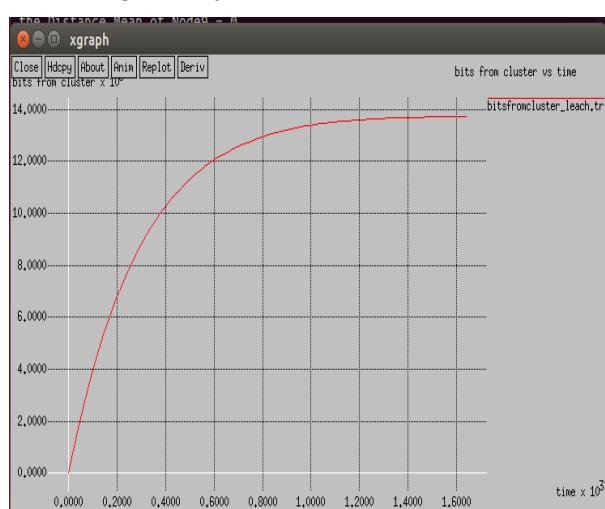

Figure 9: Bits from cluster vs. time

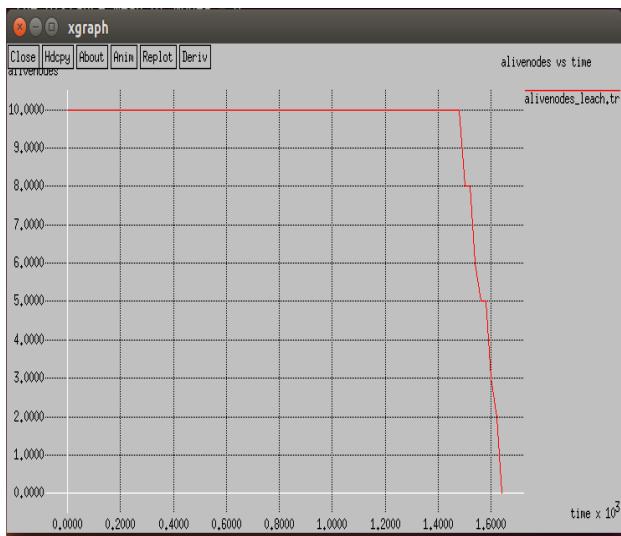

Figure 11: Alive nodes vs. time

VII. CONCLUSION

In the first scenario we ran the simulations to determine the number of bits from cluster with respect to time it is found that as time increases the number of bits from cluster is increased. In the second scenario, it is observed that the number of frames transmitted is decreased due to packet drop as the number of rounds is increased whereas in third case it shows that the number of nodes alive is limited to certain number of rounds according to simulation parameter set. Thus LEACH is suited for applications which involve constant monitoring and periodic data reporting.
